Peer-to-Peer Data Integration Systems

- The European Future Internet initiative envisions small and medium businesses participating in value chains and networks that emerge dynamically.
- Under this vision, the Internet will meet its promise to become a reliable, seamless and affordable collaboration and sharing platform.
- In principle, the ground is already laid for contemporary enterprises to be able to collaborate flexibly and affordably.
- However, businesses rarely share the same vocabulary and business semantics, raising the costs of B2B interoperability and collaboration.
- Small and medium enterprises cannot afford repeated data integration with new partners for ad-hoc collaboration, leaving the competitive advantage to large enterprises.

NisB: a case in point

- The NisB project (<http://www.nisb-project.eu/>) aims at easing ad-hoc data integration by harnessing the accumulative connectivity of the Web.
- NisB can help lower the burden for enterprises that deal with multiple heavy-weight and standard-setting enterprises in their value networks.
- It can also help business groups entering a new industrial sector to jointly leverage interoperability efforts.
- Fragments of interoperability information are shared and reused for establishing user-centric understanding of diverse business schemata and vocabularies.
- Bits and pieces of past experiences and practices are re-composed and orchestrated to solve new problems.

Design challenges

- Tolerance towards incomplete, erroneous or evolving information, such as occasional changes in business schemata.
- Quantifiable schema matching uncertainty analysis to allow users to be informed about the usefulness of reusing a matching.
- Keeping context in schema matchings to allow reusability.

background

- Schema matching is the task of providing correspondences between concepts describing the meaning of data in various heterogeneous, distributed data sources.
- Schema matching research has been going on for more than 25 years now, first as part of schema integration and then as a standalone research field.
- Over the years, a realization has emerged that schema matchers are inherently uncertain.
- A prime reason for the uncertainty of the matching process is the enormous ambiguity and heterogeneity of data description concepts:
 - It is unrealistic to expect a single matcher to identify the correct mapping for any possible concept in a set.

Probability theory vs. fuzzy set theory in schema matching

- Probability theory is a representative of a quantitative approaches in schema matching [12, 20, 8]
- Fuzzy set theory is a representative of a qualitative approaches in schema matching [19]
- Other approaches:
 - Interval probabilities [34]
 - Probabilistic datalog [43]
 - Information loss estimation [39]

Probability Theory

Possible world semantics

- An intuitively appealing way to define a probability space [25].
- A probability space is a triple $pred = (W, F, \mu)$ such that:
 - W is a set of possible worlds, with each possible world corresponding to a specific set of event occurrences that is considered possible. A typical assumption is that the real world is one of the possible worlds.
 - $F \subseteq 2^{|W|}$ is a σ -algebra over W . σ -algebra, in general, and in particular F , is a nonempty collection of sets of possible worlds that is closed under complementation and countable unions. These properties of σ -algebra enable the definition of a probability space over F .
 - $\mu : F \rightarrow [0, 1]$ is a probability measure over F .

Fuzzy Set Theory

Definition

- A *fuzzy set* M on a universe set U is a set that specifies for each element $x \in U$ a degree of membership using a membership function

$$\mu_M : U \rightarrow [0, 1]$$

where $\mu_M(x) = \mu$ is the fuzzy membership degree of the element x in M .

- The degree of membership of an element over all fuzzy sets M does not necessarily sum to 1.

Schema and attributes

- *schema* $S = \{A_1, A_2, \dots, A_n\}$ is a finite set of *attributes*.
- Attributes can be both simple and compound.
- Examples:
 - Simple attributes: lastName, firstName.
 - Compound attributes: creditCardInfo, combining type, cardNum, and expiry
- Is this representation too simple?
 - Metadata models use complex representations: relational databases use tables and foreign keys, XML structures have hierarchies, OWL ontologies contain general axioms.
 - Modeling the uncertainty in matching attributes, no richer representation of data models is needed.
 - Example 1: matching lastName and firstName does not require representing their composition in a compound attribute called name.
 - Example 2: when matching compound structures such as XML paths, XML paths **are** the elements we define as attributes in our schemata.

Attribute correspondences and the similarity matrix

- Let S and S' be schemata with n and n' attributes, respectively.
- Let $\mathcal{S} = S \times S'$ be the set of all possible *attribute correspondences* between S and S' .
 - \mathcal{S} is a set of attribute pairs.
 - Example: (arrivalDate, checkInDay)).
- Let $M(S, S')$ be an $n \times n'$ *similarity matrix* over \mathcal{S} .
 - $M_{i,j}$ represents a degree of similarity between the i -th attribute of S and the j -th attribute of S' .
 - $M_{i,j}$ is a real number in $(0, 1)$.
- $M(S, S')$ is a *binary similarity matrix* if for all $1 \leq i \leq n$ and $1 \leq j \leq n'$, $M_{i,j} \in \{0, 1\}$.

Schema matchers

- Similarity matrices are generated by schema matchers.
- *Schema matchers* are instantiations of the schema matching process.
- They differ mainly in the measures of similarity they employ, which yield different similarity matrices.
 - arbitrarily complex
 - use various techniques.
 - similar attributes are more likely to have similar names [29, 46].
 - similar attributes share similar domains [33, 21].
 - instance similarity as an indication of attribute similarity [5, 10].
 - experience of previous matchings as indicators of attribute similarity [28, 32, 46].

Matcher examples

Example

- Term matching compares attribute names to identify syntactically similar attributes.
- To achieve better performance, names are preprocessed using several techniques originating in IR research.
- Term matching is based on either complete words or string comparison.
- Example: relations CardInfo and HotelCardInformation.
 - The maximum common substring is CardInfo
 - the similarity of the two terms is

$$\frac{\text{length}(\text{CardInfo})}{\text{length}(\text{HotelCardInformation})} = \frac{8}{20} = 40\%.$$

Similarity Matrices Explained

- It was hypothesized and empirically validated by [35] that when encoding attribute pair similarities in a similarity matrix, a matcher would be inclined to assign a value of 0 to each pair it conceives not to match, and a similarity measure higher than 0 (and probably closer to 1) to those attribute pairs that are conceived to be correct.
- This tendency, however, is masked by “noise,” whose sources are rooted in missing and uncertain information.
- instead of expecting a binary similarity matrix the values in a similarity matrix form two probability distributions over $[0, 1]$.

Top- K

Similarity Matrices Explained

- Evaluation of more than 26,000 attribute pairs coming from 50 schema pairs.
- Attribute pairs separated to pairs reflecting attribute correspondences and those that not.
- The precedence matcher was used.
- Similarity values of correct correspondences normalized.
- Beta distribution estimations were added:
 - The beta distribution can be used to model a random phenomenon whose set of possible values is in some finite interval $[c, d]$.
 - A beta distribution has two tuning parameters, a and b .
 - $b > a$ for left-skewed density function.
 - $a > b$ for right-skewed density functions.

Similarity Matrices: Discussion

- Schema matchers often use data model semantics when determining the similarity between attributes.
 - XML structure has been used in Cupid [33] to support or dispute linguistic similarities.
 - Similarity flooding [38] uses structural links between attributes to update linguistic similarities.
- Once this similarity has been determined and recorded in the similarity matrix, the original semantics that derived it is no longer needed.

Schema Level Constraints

- $\Gamma : \Sigma \rightarrow \{0, 1\}$ is a boolean function that captures the application-specific constraints on schema matchings:
 - cardinality constraints.
 - inter-attribute correspondence constraints
- Γ partitions Σ into two sets, valid and invalid:
 - The set of all *valid* schema matchings in Σ is given by $\Sigma_\Gamma = \{\sigma \in \Sigma \mid \Gamma(\sigma) = 1\}$
 - (go to Slide 2.5)
- Γ is a general constraint model, where $\Gamma(\sigma) = 1$ means that the matching σ can be accepted by a designer.
- Γ has been modeled in the literature using special types of matchers called *constraint enforcers* [31], whose output is recorded in a binary similarity matrix.
- Γ is a *null constraint function* if for all $\sigma \in \Sigma$, $\Gamma(\sigma) = 1$.

Schema Matching and Matrix Satisfaction

Definition (Matrix Satisfaction)

Let $M(S, S')$ be an $n \times n'$ similarity matrix over \mathcal{S} . A schema matching $\sigma \in \Sigma$ is said to *satisfy* $M(S, S')$ (denoted $\sigma \models M(S, S')$) if $(A_i, A'_j) \in \sigma \rightarrow M_{i,j} > 0$.

$\sigma \in \Sigma_\Gamma$ is said to *maximally satisfy* $M(S, S')$ if $\sigma \models M(S, S')$ and for each $\sigma' \in \Sigma_\Gamma$ such that $\sigma' \models M(S, S')$, $\sigma' \subset \sigma$.

- The output of a schema matching process is $M(S, S')$.
- An attribute pair (A_i, A_j) is an attribute correspondence in the output schema matching only if $M(i', j) > 0$.
- A schema matching σ satisfies M if the above is true for any attribute pair in σ .
- the output of the schema matching process is a valid schema matching that **maximally** satisfies $M(S, S')$.

Top- K

Matrix Satisfaction: Discussion

- Σ is partitioned into two sets, based on satisfaction.
- Partition is based on the application and the matcher's ability to determine attribute requirements.
- compare with Γ partitioning of Σ in Slide 2.2, the two may not overlap.
- Maximal satisfaction is defined over valid schema matchings only:
 - In the absence of a constraint function Γ , *i.e.*, whenever $\Sigma_{\Gamma} = \Sigma$ or whenever Γ is ignored by the matcher, there is exactly one schema matching that maximally satisfies M .
 - This schema matching contains all attribute correspondences (A_i, A'_j) for which $M_{i,j} > 0$.
 - When Γ is both meaningful and used by the matcher, there may not be exactly one valid schema matching that maximally satisfies M .
 - Example: a 1 : 1 constraint.
 - Example: none of the valid schema matchings satisfy M .

Second-Line Matchers

Definition

Given schemata S and S' , we denote by $\mathcal{M}(S, S')$ the (possibly infinite) set of similarity matrices $M(S, S')$. A second-line schema matcher

$$SM : \mathcal{M}(S, S')^+ \times \Gamma \rightarrow \mathcal{M}(S, S')$$

is a mapping, transforming one (or more) similarity matrices into another similarity matrix.

- A second-line matcher (2LM) is a schema matcher whose inputs are no longer the schemata S and S' , but rather a similarity matrix $M(S, S')$ (together with Γ).
- *First-line schema matchers* (1LM) operate on the schemata themselves, using semantics of the application.

Second-Line Matchers: examples

Example

- Combined is a weighted combination of the Term, Value, Composition, and Precedence matchers.
- The Maximum Weighted Bipartite Graph (MWBG) algorithm and the Stable Marriage (SM) algorithm both enforce a cardinality constraint of 1 : 1.
 - MWBG uses a bipartite graph, where nodes in each side of the graph represent attributes of one of the schemata, and the weighted edges represent the similarity measures between attributes. Algorithms such as those presented in [23] provide the output of the MWBG heuristic.

Second-Line Matchers: examples

Example

- (MWBG) and SM (cont.):
 - SM takes a similarity matrix and applies a stable marriage algorithm [26] to identify a schema matching.
 - Intersection [36] computes and outputs the intersection set of both algorithm outputs.
 - Union includes in the output matching any attribute correspondence that is in the output of either MWBG or SM.
 - Intersection and Union do not enforce 1 : 1 matching.
- Dominants chooses *dominant pairs*, those pairs in the similarity matrix with maximum value in both their row and their column.
- 2LNB [35] is a 2LM that uses a naïve Bayes classifier over matrices to determine attribute correspondences.

Second-Line Matchers: examples

Example (eTuner)

- A model of a 1 : 1 matching system was defined by [31] to be a triple, one element being a library of matching components.
- This library has four types of components: Matcher, Combiner, Constraint Enforcer, and Match Selector.
 - *Matcher* is a 1LM, in its classical definition.
 - *Combiner* [9] follows the definition of a schema matcher with a null constraint function.
 - *Constraint enforcer* is a 2LM (current definition in Section 2 allows adding constraints at 1LM as well)
 - *Match selector* returns a matrix in which all elements that are not selected are reduced to 0, e.g. using thresholding and MWBG.

Second-Line Matchers: examples

Example (Top-K)

- A heuristic that utilizes the top- K best schema matchings to produce an improved schema matching [18].
- It is a special type of a combiner and a match selector.
- The input does not come from different matchers.
- Multiple matrices by same schema matcher are aggregated to a single similarity matrix by thresholding.

Discussion

- The modeling of 2LM can serve as a reference framework for comparing various research efforts in schema matching.
- Example: Combiners and match selectors were combined and redefined by [18].
- 2LMs aim at improving the outcomes of 1LMs.

Schema Matcher Classification

- A matcher is decisive if it satisfies Γ .
- Most common: non-decisive first-line matcher.
- Combiners (COMA's term) are non-decisive 2LMs.
 - Combine similarity matrices of other matchers
 - The similarity matrix is not meant to be used to decide on a single schema matching.
- Decisive 2LMs: algorithms like MWBG and SM.
 - Both are constraint enforcers [31].
 - Both enforce a cardinality constraint of 1:1.
- First-line decision makers contains few if any matchers.
 - "The comparison activity focuses on primitive objects first...; then it deals with those modeling constructs that represent associations among primitive objects." [3]
 - This dichotomy has in the main been preserved in schema matching as well.

Deep Web Information

- The deep Web hides information behind Web forms.
- This information is stored in databases on the server side.
- The database schemata are not known but the information they contain is exposed to users.
- This information can be extracted and matched.
- matrix rows represent the fields of one form and matrix columns those of the other.
- Each entry in the matrix represents the similarity of two fields.
- Possible matchers:
 - Linguistic similarity of labels
 - Linguistic similarity of field names
 - Domain similarity.
 - structural similarities: composition and precedence.

Semantic Matching

- Pairwise matching results in an ontological relationship (e.g., equivalence and subsumption) between attributes.
- The S-Match system [24] takes two graph-like structures (e.g., XML schemata) as input.
- S-Match generates a confidence measure for semantic relationship being equivalence, subsumption, *etc.*
- For each pair of elements only one relationship holds.
- Matrix representation:
 - Each ontological relationship in a separate matrix..
 - A second-line matcher (specific to S-Match) generates a set of binary matrices, using some thresholds.
 - A constraint enforcer uses a lattice structure (where, for example, equivalence is higher than subsumption) to determines which values are to remain 1.
 - An entry for which a 0 value is recorded in all matrices is assigned 1 for the *idk* (stands for “I don’t know”) matrix.

Holistic Matching

- Rather than matching two schemata at a time, holistic matching matches multiple schemata in an attempt to reach a consensus terminology for a domain.
- Representation: multi-dimensional matrices.
- Example: holistic matching of three schemata uses a 3-dimensional matrix where each entry represents the certainty of three attributes, one from each schema, being matched.

Precision and Recall

- The evaluation of schema matchings is performed with respect to an *exact matching*, based on expert opinions.
- *Precision* and *recall* are used for the empirical evaluation of performance.
- Given $n \times n'$ attribute pairs:
 - $c \leq n \times n'$ attribute correspondences, with respect to the exact matching.
 - $t \leq c$ is the number of pairs, out of the correct correspondences, that were chosen by a matcher.
 - $f \leq n \times n' - c$ is the number of incorrect correspondences.
- Precision:

$$P = \frac{t}{t + f}$$

- Recall:

$$R = \frac{t}{c}$$

- Higher values of both precision and recall are desired.

Precision and Recall

- Derivatives of precision and recall (cont.):

- error*:

- It was used by [41] for schema matching, following [15].
- Formula:

$$ER = 1 - \frac{(1 + b^2)PR}{b^2P + R}$$

- b is a tunable parameter.
- The lower the value of ER , the better the match.

- information loss*: [39]

- Quantifies the uncertainty that arises in the face of possible semantic changes when translating a query across different ontologies.
- Formula:

$$LS = 1 - \left(\frac{1}{\gamma P^{-1} + (1 - \gamma) R^{-1}} \right)$$

- γ is a tunable parameter.

The monotonicity principle

- The monotonicity measure [19], provides a relationship between the behavior of a given matcher and its true performance.
- Instead of just observing the final outcome provided by the matcher, the monotonicity principle observes the internal mechanism that leads to a matcher's decision.
- In that sense, it offers a deeper understanding of a matcher's capability.

Matcher monotonicity definition

- Equivalence schema matching classes on 2^S :
- Two matchings σ' and σ'' belong to a class p if $P(\sigma') = P(\sigma'') = p$, where $p \in [0, 1]$.
- For each two matchings σ' and σ'' , such that $P(\sigma') < P(\sigma'')$, we can compute their schema matching level of similarity, $\Omega(\sigma')$ and $\Omega(\sigma'')$.

Definition

A matching algorithm is *monotonic* if for any two matchings $\{\sigma', \sigma''\} \subseteq 2^S$, $P(\sigma') < P(\sigma'') \rightarrow \Omega(\sigma') < \Omega(\sigma'')$.

- Intuitively, a matching algorithm is monotonic if it ranks all possible schema matchings according to their level of precision.

Matcher monotonicity explained

- A matching algorithm is monotonic if it ranks all possible schema matchings according to their level of precision.
- A monotonic matching algorithm easily identifies the exact matching:
 - Let σ^* be the exact matching, then $P(\sigma^*) = 1$.
 - For any other matching σ' , $P(\sigma') < P(\sigma^*)$.
 - Therefore, if $P(\sigma') < P(\sigma^*)$ then from monotonicity $\Omega(\sigma') < \Omega(\sigma^*)$.
 - All one has to do then is to devise a method for finding a matching σ^* that maximizes Ω .

Matcher monotonicity explained

- The figure provides an illustration of the monotonicity principle using a matching of a simplified version of two Web forms.
- Both schemata have nine attributes, all of which are matched under the exact matching.
- Given a set of matchings, each value on the x-axis represents a class of schema matchings with a different precision.
- The z-axis represents the similarity measure.
- The y-axis stands for the number of schema matchings from a given precision class and with a given similarity measure.

Matcher monotonicity: insights

- The similarity measures of matchings within each schema matching class form a “bell” shape, centered around a specific similarity measure.
 - This behavior indicates a certain level of robustness, where the schema matcher assigns similar similarity measures to matchings within each class.
-
- The “tails” of the bell shapes of different classes overlap.
 - Therefore, a schema matching from a class with lower precision may receive a higher similarity measure than one from a class with higher precision.
 - Contradiction to monotonicity.

Statistical monotonicity

Definition (Statistical monotonicity)

Let $\Sigma = \{\sigma_1, \sigma_2, \dots, \sigma_m\}$ be a set of matchings over schemata S_1 and S_2 with n_1 and n_2 attributes, respectively, and define $n = \max(n_1, n_2)$. Let $\Sigma_1, \Sigma_2, \dots, \Sigma_{n+1}$ be subsets of Σ such that for all $1 \leq i \leq n+1$, $\sigma \in \Sigma_i$ iff $\frac{i-1}{n} \leq P(\sigma) < \frac{i}{n}$. We define M_i to be a random variable, representing the similarity measure of a randomly chosen matching from Σ_i . Σ is *statistically monotonic* if the following inequality holds for any $1 \leq i < j \leq n+1$:

$$\bar{\Omega}(M_i) < \bar{\Omega}(M_j)$$

where $\bar{\Omega}(M)$ stands for the expected value of M .

Statistical monotonicity

- A schema matching algorithm is statistically monotonic with respect to two given schemata if the expected certainty increases with precision.
- Statistical monotonicity can help explain certain phenomena in schema matching:
 - It can explain the lack of “industrial strength” [6] schema matchers.
 - It serves as a guideline as we seek better ways to use schema matchers.
 - It helps understanding why schema matcher ensembles work well
 - It serves as a motivation for seeking top- K matchings.

Motivation

- In an effort to increase the robustness of individual matchers in the face of matching uncertainty, researchers have turned to schema matcher ensembles.
- Ensembles combine different schema matchers that use complementary principles to judge the similarity between concepts.
- An ensemble of complementary matchers can potentially compensate for the weaknesses of any given matcher in the ensemble.
- Several studies report on encouraging results when using schema matcher ensembles (e.g., [9, 14, 21, 33, 42]).
- Tools developed for ensemble design include eTuner [31], LSD [10] and OntoBuilder [35, 37].

The Art of Matcher Ensembling

- A *schema matching ensemble* is a set of schema matchers.
- An ensemble aggregates the similarities assigned by individual matchers to reason about the resulting aggregated ranking of alternative matchings.
- Such an aggregation can be modeled in various ways:
 - A cube, aggregated into a matrix by aggregating the similarity values of each correspondence across ensemble members. [9]
 - Extended by analyzing the relationships between local and global aggregators. [11]
 - Local aggregators combine the similarity measures of attribute correspondences into a schema matching similarity measure by a single matcher.
 - Global aggregator combine the similarity measures of multiple matchers.

The Art of Matcher Ensembling

Execution dimension

- To date, *parallel ensembling* dominates the ensemble research:
 - Combine the judgments of multiple matchers (a similarity cube) into a single matcher (a similarity matrix).
 - eTuner [31] tunes the weights of the different matchers, giving greater weight to more effective matchers.
- Less common is the *sequential ensemble approach*:
 - Matchers are added to an ensemble sequentially, based on the outcomes of earlier stages.
 - Allows matchers to suggest correspondences in “regions” of the similarity matrix in which they “feel” more confident.
 - A matcher can identify correspondences for which it is less confident and pass them on to another matcher.
 - A matcher needs to be able to identify its “strong regions.”
 - An example of this line of work is that of [13], which introduces a decision tree to combine matchers.

Constructing Ensembles

- Choosing among schema matchers is far from trivial.
 - The number of schema matchers is continuously growing, and this diversity by itself complicates the choice of the most appropriate tool for a given application domain.
 - Empirical analysis shows that there is not (and may never be) a single dominant schema matcher that performs best, regardless of the data model and application domain [19].
- Most research work devoted to constructing ensembles deals with setting the relative impact of each participating matcher. For example, Meta-Learner [10] aims at a weighted average of the decisions taken by the matchers in an ensemble, using least-square linear regression analysis [10]

Boosting Ensembles

- Research has shown that many schema matchers perform better than random choice.
- We argue that any (statistically) monotonic matcher is a *weak classifier* [45]—a classifier that is only slightly correlated with the true classification.
- A *weak classifier* for binary classification problems is any algorithm that achieves a weighted empirical error on the training set which is bounded from above by $1/2 - \gamma$, $\gamma > 0$ for some distribution on the dataset (the dataset consists of weighted examples that sum to unity).
- A weak classifier can produce a hypothesis that performs at least slightly better than random choice.
- The theory of weak classifiers has led to the introduction of *boosting* algorithms (e.g., [45]) that can strengthen weak classifiers to achieve arbitrarily high accuracy.

AdaBoost

- The AdaBoost algorithm [17] is the most popular and historically most significant boosting algorithm.

Algorithm 1 Boosting

```
1: Input:  $S = \{(x_1, y_1), \dots, (x_m, y_m)\}$ , and a space hypotheses  $\mathcal{H}$ .
2: /*  $\forall 1 \leq i \leq m, x_i \in \mathcal{X}$ , and  $\forall 1 \leq i \leq m, y_i \in \{-1, +1\}$  */
3: /* initialization: */
4: for all  $1 \leq i \leq m$  do
5:    $D_1(i) = 1/m$ 
6: end for
7:  $t = 1$ 
8: repeat
9:   /* training phase: */
10:  Find the classifier  $h_t : \mathcal{X} \rightarrow \{-1, +1\}$ ,  $h_t \in \mathcal{H}$  that minimizes the error with respect to the
    distribution  $D_t$ :  $h_t = \arg_{h_j} \min \varepsilon_j$ .
11:  if  $\varepsilon_t \leq 0.5$  then
12:    Choose  $\alpha_t \in R$ .  $\alpha_t = \frac{1}{2} \ln \frac{1 - \varepsilon_t}{\varepsilon_t}$ 
13:    Update  $D_{t+1}(i) = \frac{D_t(i) \exp(-\alpha_t y_i h_t(x_i))}{Z_t}$  where  $Z_t$  is a normalization factor
14:     $t = t + 1$ 
15:  end if
16: until  $t = T$  or  $\varepsilon_t > 0.5$ 
17: /* upon arrival of a new instance: */
18: Output the final classifier:  $H(x) = \text{sign}(\sum_{k=1}^{\min(t, T)} \alpha_k h_k(x))$ 
```

AdaBoost explained

- The input to a boosting algorithm is a **set** of m examples where each example (x_i, y_i) is a pair of an instance x_i and the classification of the instance mapping, y_i .
- y_i typically (though not always) accepts a binary value in $\{-1, +1\}$, where -1 stands for an incorrect classification and $+1$ stands for a correct classification.
- The last input element is a hypothesis space \mathcal{H} , a set of weak classifiers.
- The algorithm works iteratively. In each iteration the input set is examined by all weak classifiers.
- From iteration to iteration the relative weight of examples changes.
- Most weight is set on the examples most often misclassified in preceding steps.

AdaBoost explained (cont.)

- The algorithm assign an initial equal weight to all examples. Weights are updated later
- Weak classifiers are applied in parallel, looking for the most accurate h_t over the weighted examples.
- The amount of error of each weak classifier is computed.
- The error measure is in general proportional to the probability of incorrectly classifying an example under the current weight distribution ($\Pr_{i \sim D_t} (h_t(x_i) \neq y_i)$).
- At round t , the weak classifier that minimizes the error measure of the current round is chosen.
- The stop condition limits the amount of error to no more than 50%.
- The stop condition also restricts the maximum number of iterations.

AdaBoost explained (cont.)

- The amount of change to example weights α_t is determined in a way that reduces error most rapidly (in a greedy way) [16] by minimizing

$$Z_t = \sum_{i=1}^m D_t(i) e^{-\alpha_t y_i h_t(x_i)}.$$

- The learned weights are then used to classify a new instance x , by producing $H(x)$ as a weighted majority vote, where α_k is the weight of the classifier chosen in step k and $h_k(x)$ is the decision of the classifier of step k .

The example set

- The example set $\{(x_i, y_i)\}$ consists of a set of attribute pairs (x_i is a pair!), comprising one attribute from each schema and belonging to the classification of the instance mapping y_i .
- Such a pair represents an attribute correspondence.
- Each instance x_i can be correct (*i.e.*, belonging to the exact matching) or incorrect.
- Therefore, y_i can have two possible values: $(+1)$ (for a correct matching) and (-1) (for an incorrect matching).
- This approach can be easily extended to select multiple attributes from each schema, as long as the matcher itself can assess the similarity measure of multiple attributes.
- For holistic matching, examples can be designed to be sets of attributes from multiple schemata rather than a pair.

The hypothesis space

- Choosing the hypothesis space is more tricky.
- The input to SMB is a similarity matrix $M(S, S')$ (together with Γ , the constraint enforcer function).
- Given schemata S and S' , we denote by $\mathcal{M}(S, S')$ the (possibly infinite) set of similarity matrices $M(S, S')$.
- The SMB heuristic is a mapping

$$\text{SMB} : \mathcal{M}(S, S')^* \times \Gamma \rightarrow \mathcal{M}(S, S'),$$

transforming one (or more) similarity matrices into another similarity matrix.

- Elements of the hypothesis space are matrices.

The error measure ε

- A matcher can either determine a correct attribute matching to be incorrect (false negative) or it can determine an incorrect attribute matching to be correct (false positive).
- Let A_t denote the total weight of the false negative examples, C_t the total weight of the false positive examples, and B_t the total weight of the true positive examples, all in round t .
- Typically, one would measure error in schema matching in terms of precision and recall, translated into boosting terminology as follows:

$$P(t) = \frac{B_t}{C_t + B_t}; R(t) = \frac{B_t}{A_t + B_t} \quad (1)$$

The error measure ε : cont.

- These are combined using F-Measure:

$$FM(t) = \frac{2B_t}{A_t + C_t + 2B_t} \quad (2)$$

- A plausible error measure for the SMB heuristic is:

$$\varepsilon_t = 1 - FM(t) = 1 - \frac{2B_t}{A_t + C_t + 2B_t} = \frac{A_t + C_t}{A_t + C_t + 2B_t} \quad (3)$$

- Empirical evaluation suggests that Eq. 3 performs better than other error measures.

Example of SMB

Example

This example is due to [22].

- Given the hypothesis space \mathcal{H} as described above, and given a dataset of size 70, the SMB heuristic performs 5 iterations.
- First, it creates a dataset with equal weight for each mapping.
- In the first iteration, it picks (Composition, Dominants), which yields the most accurate hypothesis over the initial weight distribution ($\varepsilon_1 = 0.328 \Rightarrow \alpha_1 = 0.359$).
- In the second iteration, the selected hypothesis is (Precedence, Intersection) with $\varepsilon_2 = 0.411$ and $\alpha_2 = 0.180$.

Example

- Given a new attribute pair (a, a') to be considered, each of the weak matchers contributes to the final decision such that its decision is weighted by its strength.
- If the final decision is positive, the given attribute pair is classified as an attribute correspondence. If not, it will be classified as incorrect.

Motivation

- Top- K schema matchings are intuitively defined as a ranked list of the best K schema matchings a matcher can generate.
- The formal definition is recursive, providing interesting insights into the behavior patterns of matchers.
- Top- K schema matchings play a pivotal role in managing uncertain schema matching.
- The effectively unlimited heterogeneity and ambiguity of data description suggests that in many cases an exact matching will not be identified as a best matching by any schema matcher.
- Top- K schema matchings are useful:
 - Creating a search space in uncertain settings.
 - Assigning probabilities in probabilistic schema matchings.
 - Improving the precision of matching results.

Definition

- Let $G = (X, Y, E)$ be an undirected bipartite graph with nodes representing attributes of two schemata and edges representing the degree of similarity between attributes.
- Assume a problem instance with a positive weight function $\varpi : E \rightarrow (0, 1]$ defined on edges.
- We are given a schema matcher and a similarity matrix M , $\varpi(i, j) = M_{i,j}$.
- G contains no edges with 0 weight.
- A matching σ is a subset of G 's edges, $\sigma \subseteq E$.
- $\sigma \subseteq E$ is equivalent to $\sigma \in \Sigma$.
- The weight of a matching σ is $f(\sigma, M)$
- Given a constraint specification Γ , we consider only valid schema matchings in Σ_Γ .

Definition: cont.

- Top- K schema matchings is defined recursively.
- For $K = 1$, the K -th best matching σ_1^* is any maximum weight matching in G satisfying

$$\forall \sigma \subseteq E, f(\sigma, M) \leq f(\sigma_1^*, M).$$

- Let σ_i^* denote the i -th best matching, for any $i > 1$.
- Given the best $i - 1$ matchings $\sigma_1^*, \sigma_2^*, \dots, \sigma_{i-1}^*$, the i -th best matching σ_i^* is a matching of maximum weight over matchings that differ from each of $\sigma_1^*, \sigma_2^*, \dots, \sigma_{i-1}^*$.
- Given top- K matchings, any matching $\sigma \subseteq E$ such that $\sigma \notin \{\sigma_1^*, \sigma_2^*, \dots, \sigma_K^*\}$ satisfies

$$f(\sigma, M) \leq \min_{1 \leq j \leq K} f(\sigma_j^*, M) = f(\sigma_K^*, M).$$

Intuitive interpretation

- Suppose an edge weight represents a matcher's belief in the correctness of an attribute correspondence, where a higher weight indicates greater confidence.
- When switching from the i -th best matching to the $(i + 1)$ best matching, the matcher is forced to give up at least one attribute correspondence, while maintaining an overall high confidence in the matching.
- To do so, the matcher cedes an attribute correspondence in which it is less confident.
- Generating top- K matchings can be seen as a process by which a matcher iteratively abandons attribute correspondences in which it is less confident.
